False-Spoof Enrichment Bug

Executive Summary

Bot defense based on User-Agent strings fails in both directions simultaneously. Hostile cloud scanners are systematically forging distinct search and AI crawler identities to probe sensitive CMS paths, config endpoints, and user credentials. Across a seven-day forensic study of 903,771 origin requests on eight anonymized B2B publishing and technical intelligence properties, we tracked 2,132 spoofed hits spanning 22 different official search and AI bot identities.

Conversely, the industry's default response to bot traffic—naive path-triggered Web Application Firewall (WAF) rules and incomplete IP/rDNS enrichment pipelines—traps legitimate, CIDR-verified crawlers. This defensive collateral damage caused publishers to silently and automatically quarantine 7,355 verified crawler hits, severing their own sites from indexing by Google, Anthropic, OpenAI, Microsoft, and Amazon. The findings reveal a critical structural gap in modern edge defense architectures.

1. Why User-Agent Defense Fails in Both Directions

The core mechanism of traditional bot mitigation heavily weights the HTTP User-Agent string. But in late 2026, relying on unverified string matching allows hostile scanners a trivial cloaking mechanism. Our logs show scanners routinely presenting themselves as Googlebot, ChatGPT-User, PerplexityBot, and Claude-SearchBot while probing for vulnerabilities like .env files or known plugin exploits. Because many edge configurations blindly trust recognized bot strings to prevent SEO disruptions, these malicious probes often bypass primary rate-limiting and WAF filters.

On the flip side, when security teams realize they are being attacked by "AI bots," the instinct is to enact strict path bans (e.g., banning any bot that touches a standard CMS shortlink parameter, remote publishing head discovery link, or oEmbed endpoint). However, legitimate AI crawlers like ClaudeBot and Googlebot organically follow these exact discovery paths during normal indexation. When a WAF triggers a quarantine based on path interaction without first fully verifying the IP against authoritative vendor CIDR lists or executing an uncapped forward-confirmed reverse DNS (FCrDNS) and ASN lookup, the result is a catastrophic collateral ban of the very systems driving modern web traffic and visibility.

KEY TAKEAWAY FOR SECOPS & SEO TEAMS

If your bot defense architecture relies on User-Agent matching or naive path-based bans without rigorous, multi-layer IP verification (CIDR, FCrDNS, ASN), you are simultaneously letting hostile scanners in and blocking legitimate AI search indexers out. Verification must precede quarantine.

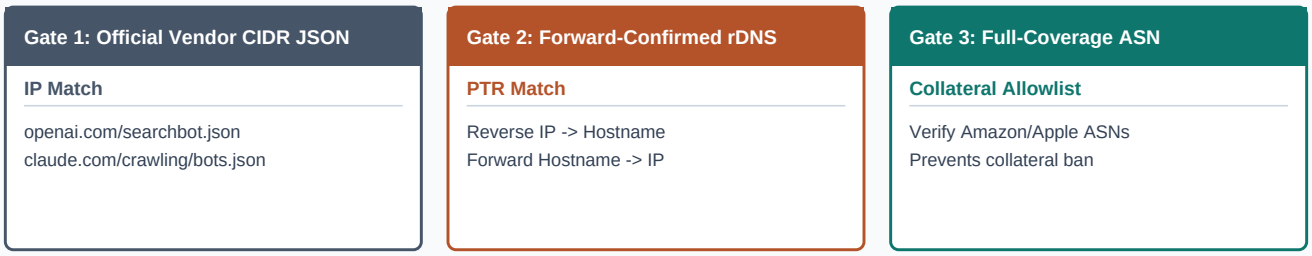
2. Anatomy of Forged AI Crawler Bursts vs. Multi-Layer Verification

When attackers deploy spoofed AI crawler identities, the execution is rarely a slow, stealthy drip. The logs reveal intense, high-velocity bursts from single cloud IP addresses explicitly designed to cycle through multiple trusted identities in an attempt to find one that bypasses edge WAF rules. These scanners iterate through lists of known good User-Agents, pairing them with aggressive vulnerability scanning tactics.

By tracking specific IP-to-UA rotation patterns, the origin telemetry uncovers the true scale and speed of these evasion techniques. The data demonstrates that static User-Agent blocklists or allowlists are functionally obsolete against modern cloud infrastructure scanning. The key empirical findings include:

- **Widespread Identity Forgery:** We observed 22 distinct forged identities across 8 out of 8 monitored properties. Attackers are not just spoofing Google; they are actively mimicking the entire modern AI ecosystem, including Anthropic, OpenAI, Perplexity, and specialized search indexers.
- **Extreme UA Rotation Velocity:** In one incident, a single IP rotated 33 distinct spoofed bot UAs across 229 hits in just 21.0 seconds. Another instance showed 47 distinct UAs rotated in 98.0 seconds, highlighting the automated, programmatic nature of the evasion.
- **Anonymized Attacker Telemetry:** Crucially, while the behavior is flagrant, standard web logging exposes 0 attacker or server IPs to the public internet, meaning threat actors operate with high impunity from generic cloud hosting providers unless strictly verified.

FIGURE 1: 3-GATE VERIFICATION PIPELINE



The 3-Gate Verification Pipeline

To combat both spoofing and collateral damage, a robust defense must implement a strict 3-Gate Verification Pipeline. Gate 1 matches the incoming IP against Official Vendor CIDR JSON feeds (e.g., openai.com/searchbot.json or claude.com/crawling/bots.json). If that fails or is unavailable, Gate 2 requires Forward-Confirmed rDNS (FCrDNS) to verify the hostname matches the IP. Finally, Gate 3 acts as a safety net, using Full-Coverage ASN mapping and a collateral allowlist to verify known ASNs (like Amazon or Apple) before any path-based quarantine is applied.

3. 12-Row Top Spoofed Identities & Collateral-Trap Matrix

The following matrix details the top spoofed AI crawler identities observed over a 7-day window, contrasted with the collateral ban hits where legitimate, verified bots were trapped by misconfigured security rules.

Identity	Spoofed (7d)	Collateral Ban (7d)	Verification Method
Spoofed-Googlebot	321	2,512	rDNS / Google JSON
Spoofed-ChatGPT-User	212	0	OpenAI JSON
Spoofed-Bingbot	109	218	rDNS / Bing JSON
Spoofed-GrokBot	95	0	ASN
Spoofed-Qwenbot	92	0	Alibaba ASN
Spoofed-ClaudeBot	88	3,427	Anthropic JSON
Spoofed-PerplexityBot	87	0	Perplexity JSON
Spoofed-GPTBot	86	1,120	OpenAI JSON
Spoofed-OAI-SearchBot	84	0	OpenAI JSON
Spoofed-Amazonbot	83	33	Amazon ASN
Spoofed-Applebot	80	13	Apple ASN / rDNS
AzureAI-SearchBot	0 (Spoofed)	1,038 (ASN Bug Case)	Microsoft ASN

4. Why Partial ASN/rDNS Lookups Create Phantom Spoof Alarms

The data highlights a severe vulnerability in how enrichment pipelines process IP data. A glaring example is the 1,038 AzureAI-SearchBot hits. A /24 ASN prefix parsing defect (which only provided 12.65% coverage) caused 1,038 legitimate Microsoft AS8075 hits to be misclassified entirely as Spoofed-AzureAI-SearchBot. When the pipeline was corrected to restore 99.98% ASN coverage, all 1,038 hits were returned to verified status. Incomplete data structures generate massive false positives.

Similarly, artificial limits on reverse DNS lookups create phantom spoofing spikes. Defaulting rDNS lookups to a cap of 400 IPs produced false Spoofed-Baiduspider spikes (jumping from 475 to 9 on one site, and 127 to 0 on another). Uncapping PTR resolution to 15,340 IPs eliminated these phantom alarms. Furthermore, on one property, a premature "Pass 1B" quarantine caused 39 out of 40 flagged Spoofed-Googlebot hits to be collateral damage—genuine .googlebot.com IPs banned for touching standard CMS paths, leaving only 1 true spoofer. Proper enrichment is not optional; it is the foundation of crawler defense.

5. 5-Step Verification-First Bot Defense Checklist

Engineering and content teams must transition from reactive blocking to verification-first architectures. Implement these five actionable steps to secure your origin logs without sacrificing AI search visibility:

1. **Verify Official JSONs Before Any WAF Block:** Always query the live, official CIDR JSON feeds from OpenAI, Anthropic, Google, and Perplexity. Do not apply a path-based ban until the IP fails this definitive check.
2. **Implement Uncapped FCrDNS Verification:** Rely on forward-confirmed reverse DNS for legacy search bots (Bing, Google, Apple) that do not publish comprehensive CIDR JSONs. Ensure your enrichment pipeline does not cap DNS lookups.
3. **Map Full-Coverage ASNs as a Safety Net:** Maintain updated ASN mappings for cloud providers (Amazon, Microsoft, Apple, Alibaba). If an IP matches the expected corporate ASN, treat it as a strong signal against spoofing.
4. **Actively Monitor for Collateral Quarantine:** Set up alerts for any verified crawler IP that triggers a WAF ban. Regularly audit your quarantine logs to identify legitimate bots trapped by overzealous path rules.
5. **Eliminate Strict Path Bans Without IP Context:** Never ban an IP simply for touching a standard CMS shortlink, user-sitemap index, or credential probe path. The action must be contextualized by the IP's verified identity.

Primary Verification Sources
